House Prices: Advanced Regression Techniques

Abstract:

House Price prediction is a very popular dataset for data science competition. In this dataset 79 explanatory variables describing (almost) every aspect of residential homes in Ames and Iowa. This competition challenges competitor to predict the final price of each home.

In this report my main focus is how artificial neural network performs for this kind of problems and how to improve performance of the prediction using artificial neural network. So my elaboration on that section will be much more detailed. I have divided my work in four part and they are

- Data processing where I have visualized, cleaned, handled missing data, carefully modified, removed and merged some features.
- Testing multiple model In this part I have used gradient boosting, decision tree, random forest regression, lasso and Artificial neural network on my pre processed data.
- Artificial neural network implementation In this section I have implemented ANN, performed parameter tuning, training, used grid search inside training and validate test score.
- Cross Validation In this part I have used k fold cross validation on my artificial neural network model to make sure if the Data is actually independent and to fine tune few parameters on whole dataset if the cross validation score is not same as validation score.
- Ensemble learning I have used bagging method for this section to improve my kaggle score.

Score:

Best Score : 0.12192 (using Ensemble Learning)

Additional processing to scale the data.

One hot encoding

To encode categorical integer features as a one-hot numeric array we are using one hot encoding. This will transform each value of catagories into a features and make those a column value of dataframe. Finally put binary values in the rows of those column.

In this section at first we merge train and test data (variable name predictor_cols and predictor_cols_test). We did it because there is some features in train data which is missing in test data again same thing can happen for test data too.

```
In [25]: # Convert categorical features using one-hot encoding.
def onehot(onehot_df, df, column_name, fill_na, drop_name):
    onehot_df[column_name] = df[column_name]
    if fill_na is not None:
        onehot_df[column_name].fillna(fill_na, inplace=True)

    dummies = pd.get_dummies(onehot_df[column_name], prefix="_" + column_name)
    onehot_df = onehot_df.join(dummies)
    onehot_df = onehot_df.drop([column_name], axis=1)
    return onehot_df
```

performing one hot

```
In [26]: def proceed onehot(df):
             onehot df = pd.DataFrame(index = df.index)
             onehot df = onehot(onehot df, df, "MSSubClass", None, "40")
             onehot df = onehot(onehot df, df, "MSZoning", "RL", "RH")
             onehot df = onehot(onehot df, df, "LotConfig", None, "FR3")
             onehot df = onehot(onehot df, df, "Neighborhood", None, "OldTown")

   # Divide up the years between 1871 and 2010 in slices of 20 years.
   year map = pd.concat(pd.Series("YearBin" + str(i+1), index=range(1871+i*20, 1891+i*20)) for i in range(0, 7))
   yearbin df = pd.DataFrame(index = df.index)
   yearbin df["GarageYrBltBin"] = df.GarageYrBlt.map(year map)
   yearbin df["GarageYrBltBin"].fillna("NoGarage", inplace=True)
   vearbin df["YearBuiltBin"] = df.YearBuilt.map(year map)
   yearbin df["YearRemodAddBin"] = df.YearRemodAdd.map(year map)
   onehot df = onehot(onehot df, yearbin df, "GarageYrBltBin", None, None)
   onehot df = onehot(onehot df, yearbin df, "YearBuiltBin", None, None)
   onehot df = onehot(onehot df, yearbin df, "YearRemodAddBin", None, None)
    return onehot df
# Add the one-hot encoded categorical features.
onehot df = proceed onehot(train)
onehot df = onehot(onehot df, neighborhood bin train, "NeighborhoodBin", None, None)
train processed = train processed.join(onehot df)
```

These onehot columns are missing in the test data, so drop them from the training data or we might overfit on them.

```
In [28]: onehot_df = proceed_onehot(test)
    onehot_df = onehot(onehot_df, neighborhood_bin_test, "NeighborhoodBin", None, None)
    test_processed = test_processed.join(onehot_df)
```

This column is missing in the training data. There is only one example with this value in the test set. So just drop it.

```
In [29]: test_processed.drop(["_MSSubClass_150"], axis=1, inplace=True)
```

Drop these columns. They are either not very helpful or they cause overfitting.

```
In [30]: drop_cols = [
    "_Condition2_PosN", # only two are not zero
    "_MSZoning_C (all)",
    "_MSSubClass_160",
]
train_processed.drop(drop_cols, axis=1, inplace=True)
test_processed.drop(drop_cols, axis=1, inplace=True)
```

log transform

We take the log here because the error metric is between the log of the SalePrice and the log of the predicted price. That does mean we need to exp() the prediction to get an actual sale price.

```
In [31]: target = pd.DataFrame(index = train_processed.index, columns=["SalePrice"])
    target["SalePrice"] = np.log(train["SalePrice"])
# train_processed.drop(["SalePrice"], axis=1, inplace=True)

print("Training set size:", train_processed.shape)
print("Test set size:", test_processed.shape)

Training set size: (1458, 403)
Test set size: (1459, 403)
```

Split Data for training and testing

```
In [33]: prediction_dict = dict()
    submit = False
    save_score = False

if submit :
        X_train = train_processed
        y_train = target
    else:
        X_train = X_train
        y_train = y_train
```

Testing different models

Random Forest Regressor

A random forest is a meta estimator that fits a number of classifying decision trees on various sub-samples of the dataset and uses averaging to improve the predictive accuracy and control over-fitting.

```
In [34]: my_model = RandomForestRegressor(n_estimators=500,n_jobs=-1)

my_model.fit(X_train, y_train)
prediction = my_model.predict(X_test)
if submit:
    submit_prediction = my_model.predict(test_processed)
    submit_prediction_dict['Random Forest Regressor'] = submit_prediction

prediction_dict['Random Forest Regressor'] = prediction

print('root mean absolute error: ',rmse(y_test, prediction))
print('accuracy score: ', r2_score(np.array(y_test),prediction))
```

/home/navid/anaconda3/envs/tf/lib/python3.6/site-packages/ipykernel_launcher.py:4: DataConversionWarning: A column-vector y was p assed when a 1d array was expected. Please change the shape of y to (n_samples,), for example using ravel(). after removing the cwd from sys.path.

```
ann root mean absolute error: 0.12391751965552095 accuracy score: 0.9093931764105156
```

DecisionTree

Decision tree builds regression or classification models in the form of a tree structure. It breaks down a dataset into smaller and smaller subsets while at the same time an associated decision tree is incrementally developed. The final result is a tree with decision nodes and leaf nodes.

Xgboost

XGBoost stands for eXtreme Gradient Boosting. It is an optimized distributed gradient boosting library designed to be highly efficient, flexible and portable. It implements machine learning algorithms under the Gradient Boosting framework. XGBoost provides a parallel tree boosting (also known as GBDT, GBM) that solve many data science problems in a fast and accurate way.

ann root mean absolute error: 0.10926796451065869 accuracy score: 0.9295499691663187

Lasso

Lasso (least absolute shrinkage and selection operator; also Lasso or LASSO) is a regression analysis method that performs both variable selection and regularization in order to enhance the prediction accuracy and interpretability of the statistical model it produces. Lasso was originally formulated for least squares models and this simple case reveals a substantial amount about the behavior of the estimator, including its relationship to ridge regression and best subset selection and the connections between lasso coefficient estimates and so-called soft thresholding. It also reveals that (like standard linear regression) the coefficient estimates need not be unique if covariates are collinear.

```
In [50]: from sklearn.linear_model import Lasso
    my_model = Lasso(alpha=5e-3, max_iter=50000)

my_model.fit(X_train, y_train)
    prediction = my_model.predict(X_test)
    prediction_dict['Lasso'] = prediction

if submit:
    submit_prediction = my_model.predict(test_processed)
    submit_prediction_dict['Lasso'] = submit_prediction

print(' root mean absolute error: ',rmse(y_test, prediction))
    print('accuracy score: ', r2_score(np.array(y_test),prediction))

root mean absolute error: 0.10794617678311977
```

In the above model alpha is Constant that multiplies the L1 term. For numerical reason we cant set alpha to 0 but keeping alpha low provides good accuracy for out dataset. I have found 5e-4 provides good accuracy.

for 5e-5: root mean absolute error: 0.10973737757187135 accuracy score: 0.9289433650407954 for 1e-5: root mean absolute error: 0.11426822609093419 accuracy score: 0.9229546464396043 for 1e-3: root mean absolute error: 0.10466883446067998 accuracy score: 0.9353556969018821 for 1e-4: root mean absolute error: 0.10658498063306822 accuracy score: 0.9329671780226085 for 5e-3: root mean absolute error: 0.10794617678311977 accuracy score: 0.9312440935471524

accuracy score: 0.9312440935471524

ANN

Theory and Basics:

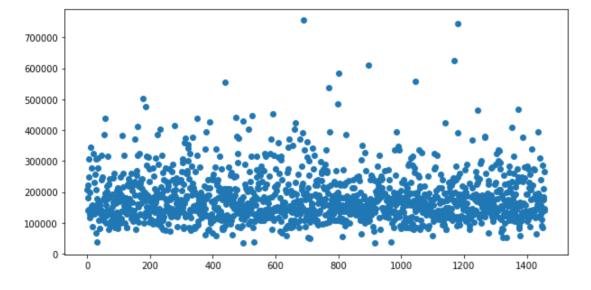

An Artificial Neurol Network (ANN) is a computational model. It is based on the structure and functions of biological neural networks. It works like the way human brain processes information. ANN includes a large number of connected processing units that work together to process information. They also generate meaningful results from it.

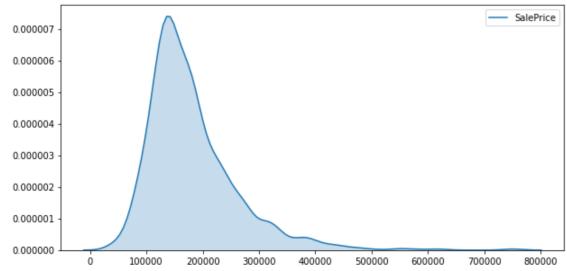

An artificial neuron is a mathematical function conceived as a model of biological neurons, a neural network. Usually each input is separately weighted, and the sum is passed through a non-linear function known as an activation function or transfer function.

The artificial Neural network is typically organized in layers. Layers are being made up of many interconnected 'nodes' which contain an 'activation function'. A neural network may contain the following 3 layers:

- Input layer The purpose of the input layer is to receive as input the values of the explanatory attributes for each observation. Usually, the number of input nodes in an input layer is equal to the number of explanatory variables. 'input layer' presents the patterns to the network, which communicates to one or more 'hidden layers'. The nodes of the input layer are passive, meaning they do not change the data. They receive a single value on their input and duplicate the value to their many outputs. From the input layer, it duplicates each value and sent to all the hidden nodes.
- Hidden Layer The Hidden layers apply given transformations to the input values inside the network. In this, incoming arcs that go from other hidden nodes or from input nodes connected to each node. It connects with outgoing arcs to output nodes or to other hidden nodes. In hidden layer, the actual processing is done via a system of weighted 'connections'. There may be one or more hidden layers. The values entering a hidden node multiplied by weights, a set of predetermined numbers stored in the program. The weighted inputs are then added to produce a single number.
- Output layer The hidden layers then link to an 'output layer'. Output layer receives connections from hidden layers or from input layer. It returns an output value that corresponds to the
 prediction of the response variable. In classification problems, there is usually only one output node. The active nodes of the output layer combine and change the data to produce the output
 values.

In [35]: import seaborn as sns
import matplotlib.pyplot as plt
plt.figure(figsize=[10,5])
plt.scatter(range(len(train)),list(train.SalePrice.values))
plt.show()
plt.figure(figsize=[10,5])
sns.kdeplot(train.SalePrice, shade= True)
plt.show()

In the above graph we can see that the price range is in a normal distribution. If we provide tf.random.normal while initializing the weight it should be more helpful for training. And this initialization should provide better validation with low amount of epoches. In my kaggle score rmse 0.123 is found through random normal while uniform distribution provided rmse 0.127 score. Again Uniform distribution takes 3 times more epoches to reach rmse score 0.127. But for uniform distribution no improvement cant found after 16000 epoch and for normal distribution no improvement can't found after 6000 epoch.

Target

By observing the span of the data and the data distribution we can conclude that logistic regression should perform well for this kind of problem. So we can safely say that starting with single neuron in a single hidden layer should perform well and we should look for simpler solution. Again from theoretical perspective single neurone and single layer ANN is nothing but a logistic regression and after adding layers and neurons we can regularize them so that they behave more like a logistic regression model and then we can tune parameter such a way so that it can handle little bit more complexity than a logistic regression. Finally my target is to make sure that it performs well as a logistic regression model and then improve it with more neuron/layers and proper tuning of parameters.

```
In [36]: # log_df = pd.DataFrame(columns=['learning_rate', 'num_steps', 'beta1','beta2','beta3', 'hidden_1' , 'hidden_2', 'hidden_3','inpu
t_dim' , 'test_rmse_score', 'test_r2_score'])
# log_df.to_csv("diffrent_training_results.csv", index=False)
```

Ann parameters

```
In [37]: | tf.reset default graph()
         learning rate = 0.1
         num steps = 6000
         #for regularize weight matrix
         beta1 = 0.1
         beta2 = 0.00
         beta3 = 0.00
         beta4 = None
         hidden 1 = 16
         hidden 2 = 8
         hidden 3 = 4
         hidden 4 = None
         # minimum validation cost is to control model saving locally
         minimum validation cost = 0.0190000
         input dim = X train.shape[1] # Number of features
                           # Because it is a regression problem
         output dim = 1
         #tf graph input
         X tf = tf.placeholder("float" )
         y tf = tf.placeholder("float" )
```

WARNING:tensorflow:From /home/navid/anaconda3/envs/tf/lib/python3.6/site-packages/tensorflow/python/framework/op_def_library.py:2 63: colocate_with (from tensorflow.python.framework.ops) is deprecated and will be removed in a future version. Instructions for updating:

Colocations handled automatically by placer.

Model

In the dataset Sales price are non negative number so our model is expected to return positive values so as a activation function I have used relu as it gives positive values. Again relu is easy to optimize because they are similar to linear units. The only difference is that a rectified linear unit outputs zero across half its domain. Thus derivatives through a rectified linear unit remain large whenever the unit is activate. The gradients are not only large but also consistent.

```
In [39]: def ann_model(X_val):
    # Hidden layers
    layer_1 = tf.add(tf.matmul(X_val, weights['w1']), biases['b1'])
    layer_2 = tf.and.relu(layer_1, weights['w2']), biases['b2'])
    layer_2 = tf.nn.relu(layer_2)

    layer_3 = tf.add(tf.matmul(layer_2, weights['w3']), biases['b3'])
    layer_3 = tf.nn.relu(layer_3)

# Output layer
layer_out = tf.add(tf.matmul(layer_3, weights['out']), biases['out'])

return layer_out
```

For optimization I have used Adam optimizer. Adam derives from phrase "adaptive moments". Its a varient of RMSProp. I have used adam instead of RMSProp for couple of reasons. First, in Adam, momentum is incorporated directly as an estimate of the first-order moment (with exponential weighting) of the gradient. The most straightforward way to add momentum to RMSProp is to apply momentum to the rescaled gradients. The use of momentum in combination with rescaling does not have a clear theoretical motivation. Second, Adam includes bias corrections to the estimates of both the first-order moments (the momentumterm) and the (uncentered) second-order moments to account for their initializationat the origin. RMSProp also incorporates an estimate of the (uncentered) second-order moment; however, it lacks the correction factor. Thus,unlike in Adam, the RMSProp second-order moment estimate may have high bias early in training. Adam is generally regarded as being fairly robust to the choice of hyperparameters, though the learning rate sometimes needs to be changed from the suggested default. Usually default rate is .001 but for our case I have used 0.1 as it gives better optimization results.

```

Grid search on epoch:

In the above block I have saved the model for the best validation score. As I mentioned earlier the epoch to reach the best validation accuracy is not fixed. Rather we can find it in 3 different range of epoch. The reason behind this is mostly because of random initializing of the weight and if we have fixed the seed value then it might change into only one single epoch range. But doing so we loose chance to improve our model further. Again if we want to ensemble different ANN model it woun't help when we use same seed and state. I have tried 1000+ parameters and combination from the start and used graph to visualize how to improve that but with grid search I might not get the exact idea why certain things provide good results or not and looking into every search result and graph is also too much so applying on the epoch seems to me more reasonable solution because the epoch for best validation result will be different in every run.

Trick

I have shuffled the data in every epoch and this trick improved the validation accuracy. On the other hand I did't use batch because according to my previous experience this kind of logistic regression problem works better when its given as a whole set rather than batch or mini-batch. But if its overfitting then passing the data in a batch / mini-batch would perform better as it helps to generalize more. We can say its more like a dropout effect. And I have tried to do dropout to reduce distance of training and validation accuracy but that didn't worked well.

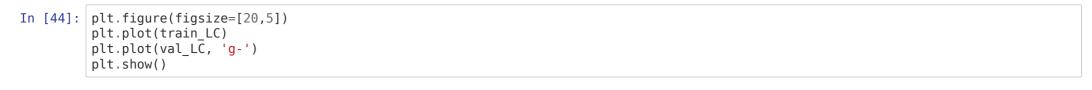

```

```

kaggle rmse:

In kaggle ranking the above ANN model provides the best rmse score and the score is 0.12324

Save score

Parameters

Following segment is actually initializing different parameters. From the dataset we can see that the estimation of sale price is a regression problem and neural network used here was overfitting most of the time due to higher variance. So for making it simpler I have penalized weight matrix of hidden layers with I2 regularization. Again I have found that single hidden layer with single neuron performs well and that means the prediction model don't need to be too complex. Thus I became ensured that regularization is going to improve performance.

Cross validation

When we perform a random train-test split of our data, we assume that our examples are independent. That means that by knowing/seeing some instance will not help us understand other instances. However, that's not always the case. So to make sure if the Data is actually independent, to get more metrics and to use fine tuning my parameters on whole dataset I am performing cross validation.

Observation

In the cross validation section we can see that 10 fold cross validation on our best ANN model provides similar rmse to 80-20 split rmse score. So we can relay on 80-20 split on this dataset. Thus we can say that the data in the dataset is independent.

Observing Few Other well performed ANN models

In this section We are observing the few other models and their learning curve. After that some of them will be used for Ensemble learning section for further improvement. In this model I have only changed the size of hidden layer, amount of neuron in each hidden layers, number of steps and learning rates. Rest of the part is same as the ANN described above.

ANN with 4 layers

Initialization of models

```
def weight bais():

accuracy score: 0.9138090324301579

Hyperparameeter tuning

Few of my hyperparameeter tuning is shown in the following block. In this data if a hidden layer value is 0 then it means that the hidden layer is turned off. For example if hidden_3 = 0 then that means hidden layer 3 is removed from the model and the model have only 2 hidden layer. And all the score is done on a validation set which is not seen by the model while training. For most of the case it was a 80-20 split. In the following results I didint kept any cross validation results but I have used diffrent seed while splitting data due to diffrent seed sometimes good hyperparameeter also provided so so accuracy.

```
In [255]: log_df = pd.read_csv("diffrent_training_results.csv")
# print(log_df.to_string())
pd.set_option('display.max_rows', None)
log_df
```

Observation and discovery:

- In the above parameter we can see that index 44 shows that for .001 learning parameter the model does not predict anything so I have changed it slowly and finally What I have found that learning parameter .1 and .05 provides the best results.
- Beta1, Beta2, Beta3, Beta4 represents the regularization parameter for hidden layer 1,2,3 and 4. Sometimes in the above table we can see that hidden layer 2,3,4 is 0 or NaN but there is some value for beta 2,3,4 that means the layer is actually off so those values actually means nothing.
- For 3 layer model when beta1, beta2, beta3 is .005, model shows significant amount of improvement while learning rate is .1 or .05. But when learning rate is .1 and beta1=.1, beta2=0, beta3=0 then the model performs even better most of the time and it also takes less epochs to train for the best validation accuracy
- From index 63 to 69 I have tried to use 200, 100, 30 neurons because the data have 403 features and its a common practice to use half amount of the neuron in the first hidden layer and this strategy does not work good enough but with my selected parameter it improved a little bit. I have used 16-8-4 combination of neuron because of this common practice. for our case 16 neuron in the first layer provided better accuracy and adding 8 and 4 in the next 2 layer improved the stability of the model and now it gives good validation accuracy after 2000 epoch and the best validation accuracy remains between the epoch range of 2000-2500, 3300-3600 or 5000-5400.
- From index 70 to 78 we can see that single neuron with single hidden layer performs well according to the plan stated in the target section. Then I have increased neurons and the learning curve for them is in the following block. Where y axis shows rmse and x axis shows i and i*50 represents the epoch no. Again blue curve is for training accuracy and green for validation accuracy
- In the table index 169 and 155 the model is exactly same with same parameter but one of them is providing .123 and other is providing .41 and that shows how inconsistent model become when we increase the neuron of the first hidden layer.
- We can see that even after adding another layer ANN does not perform well when we are increasing neurons in the first layer. The reason behind it is that this type of regression problem
 usually do well with logistic regression. By increasing neurons we cant do much improvement and all we need to do is properly regularize small amount of neurons so that they can perform
 well.

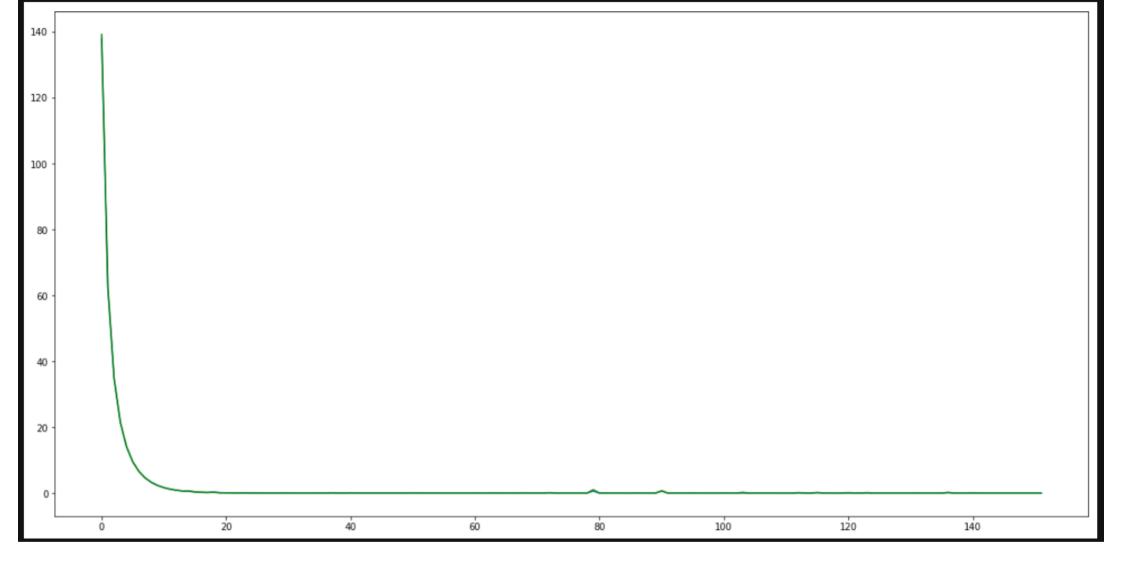

For single neuron learning rate

For 4 neuron learning curve

For 16 neuron learning curve

For 32 neuron learning curve

Ensemble

I am using bagging method for this section. Usually in this technique we add different models results and average them. But instead of averaging I am taking different fraction from different models result. Finally making sure that it sums up to 1.

I have tried different combinations of ensemble learning to improve performance. Kaggle has a certain limitation on uploading submission files. So what I have tried is that before submitting it to kaggle, I have made 80-20 split. I made prediction on the 20% data. Then I have tried ensemble learning so that before submission I can confirm which combination might work well.

Ensemble combination 4 provides the best score which is 0.12192. Currently combination 4 is showing that rmse value is .1019 and there is a better value present in combination 1 which is 0.1017. The reason behind the difference is ANN does not perform exactly same each time. That means if I currently submit with Combination 1 I might get better results than Combination 4.

In Combination 4 used models with their parameters:

Name	learning rate	beta1	beta 2	beta 3	beta 4	hidden layer 1	hidden layer 2	hidden layer 3	hidden layer 4	Fraction taken

Obesrvation

In the learning curve graph if the minimum of training and validation is close to each other then its good to use that model. Again if training minimum and validation minimum is no where near each other then using them does not help much most of the case. When both of them are close we can use the epoch no of the train_min loss as val_min loss epoch no and then we can train over all the dataset without depending on the epoch number. The model does not give same result in same epoch every time. This is the main reason behind removing the epoch dependency.

For descriptive section

I have inspired form Ian Goodfellows book and used his way of explanation to explain my choice. His book can be found here: https://www.deeplearningbook.org/
(https://www.deeplearningbook.org/)

I have also followed data flatter for definition and their lessons can be found here: https://data-flair.training/blogs/neural-network-for-machine-learning/ (https://data-flair.training/blogs/neural-network-for-machine-learning/ (https://data-flair.training/blogs/neural-network-for-machine-learning/ (https://data-flair.training/blogs/neural-network-for-machine-learning/ (https://data-flair.training/blogs/neural-network-for-machine-learning/ (https://data-flair.training/blogs/neural-network-for-machine-learning/))
